Algorithms for Computing Limit distributions of Oscillating $M^{[x]} / G / 1$ Systems with Finite Capacity

Mohammad Taremi

ABSTRACT

We address the batch arrival $M^{[x]} / G / 1$ systems with finite capacity under partial batch acceptance strategy where service times or rates oscillate between two forms according to the evolution of the number of customers in the system. Applying the theory of Markov regenerative processes and resorting to Markov chain embedding, we present a new algorithm for computing limit distributions of the number customers in the system. The numerical results are given in the paper for a clearer expression of the proposed computational methodologies.

$M^{[x]} / G / 1$ Systems, Finite Capacity, Oscillating Systems, Acceptance Strategy, Batch Arrivals

1. INTRODUCTION

One way to increase server utilization while keeping customer waiting times under control is to consider queuing systems whose characteristics (such as service rate or input rate) depend on the evolution of the state of the system (such as the number of customers in the system or the workload). For instance, Choi et al. [6], [7], Harris [14], [15], Larsen and Agrawala [21], Ramalhoto [25], Rhee and Sivazlian [26] and Welch [30] studied queuing systems whose service characteristics depend on the evolution of the number of customers; Chydzinski [9] and Takagi [28] studied queuing systems with an input rate depending on the evolution of the number of customers in the system; Ivnitskiy [16], Li [22] and Lu and Serfozo [24] studied queuing systems with input rates and service rates depending on the evolution of the number of customers in the system; Altman et al. [1] studied queuing systems with workload dependent service times; and Bekker et al. [3] and Golubchik and Lui [13] studied queuing systems in which the arrival rate and service rate depend on the system workload.

In this paper, we investigate the limit distribution of the number of customers in oscillating $M^{[x]} / G / 1$ systems with finite capacity. We use the term (service) oscillating systems in the sense used in [4], [8] and [10], i.e., as a queuing system that oscillates between two operating phases, 1 and 2, which impact the service rates or service characteristics, as described below.

The limit distribution of the number of customers in a queuing system is an important characteristic of the system, as it provides information about the evolution of its congestion level over time. Federgruen and Tijms [12] compute the limit distribution of the queue length in oscillating $M / G / 1$ systems recursively by using the theory of Markov regenerative processes (MRGP). Bratiychuk and Chydzinski [4] and Chydzinski [8] have addressed the limit analysis of the number of customers in oscillating systems with infinite capacity, and Chydzinski [10] has studied steady state characteristics of oscillating systems with single arrivals and finite capacity using the potential method.

In general terms, when an oscillating system is in phase 1 the number of customers moves between 0 and $b - 1$, and when it is in phase 2 the number of customers moves between $a + 1$ and $n$, with the integers $a$ and $b$ denoting the lower barrier and the upper barrier of the system, respectively. More precisely, if at time $t$ the system is operating in phase 1, so that the number of customers in the system is smaller than the upper barrier $b$, then the system remains in phase 1 until the first subsequent epoch at which the number of customers in the system becomes greater or equal to the upper barrier $b$. At this epoch, the system changes to phase 2 and remains in this phase until the first subsequent epoch at which the number of customers in the system becomes (smaller or) equal to the lower barrier $a$, at this time the system changes again to phase 1, and so on.

We consider two types of oscillating systems (i.e., I and II), that are characterized in terms of two distribution functions $A_1$ and $A_2$ as follows:

- In type I systems, a customer service time that is initiated in phase $j$ has distribution $A_j$, $j = 1, 2$, and is independent of the both customer arrival process and previous customer service times.

Mohammad Taremi, Department of Statistics, Faculty of Economics, Allameh Tabataba’i University, Tehran, Iran (e-mail: Mohammad20taremi@yahoo.com)
In type II systems, a customer service initiated in phase 2 has customer service time distribution $A_2$, and is independent of the both customer arrival process and previous customer service times. Conversely, a customer service initiated in phase 1 is started with service time distribution $A_1$. However, if before this service time finish the system moves to phase 2 (due to the number of customer in the system becoming greater or equal to the upper barrier $b$) then a reset of the service is done at the instant the system changes phases and an additional time with distribution function $A_3$ is added to the customer service time.

This time also is independent of the customer arrival process and of previous customer service times.

Type I oscillating systems have been addressed by several authors, including Bahary and Kolesar [2], Choi and Choi [5], Srram et al. [27], Loris-Teghem [23] and [4], [7] and [12]. In particular, type I oscillating systems introduced in [5], [7] and [27] the analysis of cell-discarding schemes for voice packets in ATM networks by allowing dropping of low-priority (less significant) bits of information during congestion periods. It is noteworthy that [22] uses similar models for overload control in message storage buffers such that both the input and service rates or characteristics may depend on the phase of the system. In addition, type II oscillating systems coincide with the queuing systems defined in [8] and [10].

In this paper, we address oscillating batch arrival $M^{[x]}/G/1$ systems with finite capacity $n$. These are queuing systems with a single server, at which customers arrive in batches, with independent and identically distributed (i.i.d) sizes, according to a Poisson process. The sequences of batch sizes and batch inter-arrival times are independent, and the system has finite capacity $n$, including the customer in service (if any). As regards the customer acceptance policy, we consider what is known as partial blocking (see e.g., Vijaya Lakmi and Gupta [29]) in which if at the arrival of a batch of $l$ customers there are only $m$, $m < l$, free positions available in the system, then $m$ customers of the batch enter the system and the remaining $l-m$ customers of the batch are blocked.

Our approach to investigate the limit distribution of the state of the system based on the fact that the state process in these systems constitutes a MRGP associated with appropriate Markov renewal sequences by means of the embedded Markov chain (EMC) (see e.g., Kendall [17], [18]). Specifically, the information on the state of the system in continuous time is obtained from the analysis of the embedded discrete time Markov chains (DTMCs) associated with the sequence Post-customer departure instants. We remark that other authors have used the theory of MRGP to derive recursive relations in $M/G/1$ systems, as, e.g., Fakinos and Economou [11] and [12].

We end this introduction with a brief outline of the paper. In Section 2, we present a Markov renewal process formed by the number of customers in the system at the departure epochs. We use this Markov chain embedding to characterize the limit distribution of the state of the system at post-customer departure epochs in Section 3 and then resort to the Markov regenerative structure of the state of the system to obtain the limit distribution of the state of the system in continuous time in Section 4. We detail in Section 5 how the computation of the limit distribution of the state of the system may be implemented for the considered system. In sequence, we provide in Section 6 numerical results for the limit distribution of the state of the system obtained using the proposed computational methodologies.

2. THE EMBEDDED MARKOV CHAIN (EMC)

We denote the oscillating batch arrival $M^{[x]}/G/1$ systems with finite capacity $n$ and with lower barrier $a$ and upper barrier $b$ as $M^{[x]}/G_{1}/\mathrm{I}/n(a,b)$ systems, the service times oscillate between two forms according to evolution of the number of customers in the system, as described in the introduction.

We assume $\dot{\lambda} (\lambda > 0)$ denote the batch arrival rate and $(f_i)_{i \in \mathbb{N}}$ denote the batch size probability function, where $N = \{1,2,3,\ldots\}$ and $f_i^{(r)}$ denotes the probability that the total number of customers in $r$ customer batches is equal to $i$. Note that $f_{0}^{(0)} = \delta_{0}$, and

$$f_{j}^{(r)} = \sum_{i=0}^{j} f_{j-i}^{(r-1)}$$

for $r \in N$, and $j = r, r+1, \ldots$, where $\delta_{i}$ is the Kronecker delta function, i.e., $\delta_{i} = 1$ if $i = j$ and $\delta_{i} = 0$ otherwise.

As mentioned in the Introduction, we let $A_{1}$ and $A_{2}$ denote the distribution function associated with operating phases 1 and 2, respectively, in $M^{[x]}/G_{1}/\mathrm{I}/n(a,b)$ systems. Moreover, we let $1/\mu_{1}$, $1/\mu_{2}$ denote the expected values of the distributions $A_{1}$ and $A_{2}$, respectively.

In addition, we let $r_{j}(A_{i})$, $j \in N = \{0,1,2,\ldots\}$, denote the probability that $j$ customers arrive during a customer service time with distribution $A_{i}$. Then, by conditioning on the number of batches arriving during a customer service time with distribution $A_{i}$, we have

$$r_{j}(A_{i}) = \sum_{\alpha_{j}} f_{\alpha_{j}}^{(r)} \alpha_{j}(A_{i}), \quad i = 1 \text{ or } 2$$

where $\alpha_{j}(A_{i})$ is $l$-th mixed-Poisson probability with arrival rate $\dot{\lambda}$ and mixing distribution $A_{i}$, i.e. (see e.g.,
\[ \alpha_i(A) = \int_0^e e^{-\lambda t} (\lambda t)^{i-1} \frac{1}{l!} A_i(dt). \]  

(3)

We also assume that \( Y = \{Y(t) = (Y_1(t), Y_2(t)), t \geq 0\} \) denotes the (continuous time) state process in \( M^x(I \to G_1 - G_2 / l / n / (a, b)) \) system, where \( Y_i(t) \) is the number of customers in the system at time \( t \) and \( Y_j(t) \) is the phase of the system at time \( t \), and \( Y \) has state space
\[ E^{(n,a,b)} = E^{(n,a,b)} \cup \{(0,1)\}, \]

with \( E^{(n,a,b)} = \{(c_i,1) : 1 \leq c_i \leq b-1\} \cup \{(c_i,2) : a+1 \leq c_i \leq n\} \).

We now use the method of the EMC and apply it to our considered systems. The fundamental idea behind this method is that we select a specific set of points in the state process \( Y \). These special epochs in this approach must have the property that, if we specify the number in the system at one such point, then at the next suitable point in time we can again calculate the number in system. There are many such sets in the state process \( Y \). An extremely convenient set of points with this property is the set of departure instants from service. Therefore, we define \( (T_m)_{m \in N^+} \) as the time sequence of customer service completion epochs, i.e., \( T_m \) is the instant at which the \( m \)-th service completion takes place. In addition, we let \( Y^p = \{Y^p = (Y^p_m, Y^p_{m+1}), m \in N\} \) denote the post-customer departure state process in this system, where \( Y^p_m = Y_1(T_m) \) is the number of customers that stay in the system after the \( m \)-th service completion and \( Y^p_{m+1} = Y_1(T_{m+1}) \) is the phase of the system after the \( m \)-th service completion. Clearly, because of the Markov property of the Poisson distribution the process \( Y^p \) is a Markov chain with discrete-parameter and because of the imbedded nature of the process it is known as an embedded Markov chain.

3. POST-CUSTOMER DEPARTURE STATE IN OSCILLATING SYSTEMS

In this section, we present the derivation of the limit distribution of the post-customer departure state in type I and type II \( M^x(I \to G_1 - G_2 / l / n / (a, b)) \) systems, i.e., the limit distribution of \( Y^p \).

Note that the transitions in state process \( Y^p \) are depending on the number of customers that arrive to the system during the successive customer service times. Thus, to characterize \( Y^p \) it is useful to first characterize the probability that \( l \) customers arrive to the system during a customer service initiated in state \( c \), denoted by \( r^{(b)}_{cl} \), for \( l \in N \) and \( c \in E^{(n,a,b)} \). In lemma 1 we show how the probabilities \( r^{(b)}_{cl} \) may be computed for both type I and type II \( M^x(I \to G_1 - G_2 / l / n / (a, b)) \) systems.

**Lemma 1:** In type I \( M^x(I \to G_1 - G_2 / l / n / (a, b)) \) systems, the \( r^{(b)}_{(i,j)} \) probabilities are computed as:
\[ r^{(b)}_{(i,j)} = \eta_i(A_j) \]

(4)

for \( (i,j) \in E^{(n,a,b)} \) and \( l \in N \), where, as defined in (2), \( \eta_i(A_j) \) is the probability that \( l \) customers arrive during a customer service time with distribution \( A_j \), and in type II \( M^x(I \to G_1 - G_2 / l / n / (a, b)) \) systems, the \( r^{(b)}_{(i,j)} \) probabilities are such that
\[ r^{(b)}_{(i,j)} = \left\{ \begin{array}{ll}
\eta_{n-i}(A_j) & \text{if } j = 1 \text{ and } 0 \leq l \leq b-1-i \\
\eta_{i}(A_j) & \text{if } j = 1 \text{ and } b-i \leq l \\
2 & \text{if } j = 2
\end{array} \right. \]

(5)

where
\[ r^{(b)}_{(m,u)}(A,B) = \sum_{u=0}^{1} q_{mu}(A)r_{(m,u)}(B), \]

(6)

for distribution functions \( A \) and \( B \) of nonnegative random variables, with \( q_{mu}(A) \), \( 1 \leq m \leq l \). denoting the probability that during a customer service with distribution \( A \), \( m \) or more customer arrivals take place and exactly \( u \) customers arrive until the first moment at which \( m \) or more customer arrivals have occurred.

Moreover,
\[ q_{mu}(A) = 2 \sum_{s=0}^{l-1} \sum_{k=0}^{m-1} \bar{f}^{(s)} f^{(n-s)}_{mu} \bar{\alpha}_s(A) \]

(7)

with
\[ \bar{\alpha}_s(A) = \int_{0}^{e^{-\lambda t}} \int_{t}^{(\infty)} \int_{(-\infty)}^{A(u)du} dt \]

(8)

denoting the \( s \)-th mixed-Poisson expected value with rate \( \lambda \) and mixing distribution \( A \), satisfying
\[ \bar{\alpha}_s(A) = 1 - \alpha_s(A) \]

(9)

\[ \alpha_s(A) = \frac{1}{\lambda} (1 - \bar{\alpha}_s(A)) \]

(10)

where \( \alpha_s(A) \), the \( s \)-th mixed-Poisson probability with rate \( \lambda \) and mixing distribution \( A \) is defined in (3).

**Proof:** In type I \( M^x(I \to G_1 - G_2 / l / n / (a, b)) \) system, we obtain (4) by considering the number of batches arriving during a customer service, as described in (2), since the customer service time distribution is \( A_l \) if the service
starts with the system in phase 1, and is $A_2$ if the service
starts with the system in phase 2. Similarly, the $r_{i,b-l}^{(b)}$
probabilities in (5) for type II $M_2^{[x]} / G_1^* - G_2^* / 1 / n(a,b)$
systems follow by conditioning on the number of batches
arriving during a customer service that starts with the
system in phase 2, which has distribution $A_2$. In the same
way, the $r_{i,b-l}^{(b)}$ probabilities, $l \leq b - i - 1$, in (5) for type
II $M_2^{[x]} / G_1^* - G_2^* / 1 / n(a,b)$ systems follow by conditioning
on the number of batches arriving during a customer service
that starts with $i$ customers in the system and the system
being in phase 1, which has distribution $A_1$ if fewer than $b-i$
customers arrive during the service time.

We now address the computation of $r_{i,b-l}^{(b)}$
probabilities, $l \geq b - i$, for type II $M_2^{[x]} / G_1^* - G_2^* / 1 / n(a,b)$
systems. These probabilities are associated to customer
services initiated in the system in phase 1 such that the
system changes from phase 1 to 2 during the customer
service. For that, let $C_m$ denote the event that during a
random time with distribution $A_1$, independent of the
customer arrival process, $m$ or more customer arrivals
take place and exactly $l$ customers arrive until the first
moment at which $m$ or more customer arrivals have
occurred, whose probability is $d_m(A_1)$. Moreover, let
$D_e$ denote the event that during a random time with
distribution $A_1$, independent of the both customer arrival
process and the events $(C_m)_{m \in \mathbb{N}}$, $u$ customer arrivals take
place, whose probability is $d_u(A_1)$. Then, for $1 \leq i \leq b-1$
and $l \geq b-i$, we have:

$$r_{i,b-l}^{(b)} = \sum_{a,b-i} P(C_{b-i,a} \cap D_{a-i}) = \sum_{a,b-i} P(C_{b-i,a})P(D_{a-i})$$
$$= \sum_{a,b-i} q_{b-i,a}(A_1) r_{i,a}(A_1) = r_{i,a}(A_1, A_1).$$

As the previous relations leads to (6), it remains to show
(7) to conclude the proof. The Equation (7) follows since,
by conditioning on the value of the product of the time it
takes to observe $m$ or more customer arrivals by the
indicator function of this time being smaller than an
independent random variable with distribution $A$, we
conclude that, for $1 \leq m \leq l$:

$$q_m(A) = \int_0^\lambda \left[ \sum_{a=0}^{m-1} e^{-a} \frac{(\lambda t)^m}{s!} \sum_{a=0}^{m-1} f_{(a)}(s) \lambda f_{(a)}(s) dt \right] A(du)$$
$$= \lambda \sum_{a=0}^{m-1} \sum_{a=0}^{m-1} f_{(a)}(s) f_{(a)}(s) \tilde{\alpha}_s(A).$$

Finally, (9) and (10) follow since, from Kwiatkowska et
al. ([20], Theorem 2),

$$\tilde{\alpha}_s(A) = \frac{1}{\lambda} \sum_{j=1}^\infty \alpha_j(A).$$

We are now able to characterize the post-customer
departure state process $Y_p$. We first note that $Y_p$ is a
DTMC with state space $E_{(n,a,b)} = \tilde{E}_{(n,a,b)} \cup \{0,1\}$
where

$$E_{(n,a,b)} = \left\{ \left( \{c_1,1\}:1 \leq c_1 \leq b-2 \right) \cup \{c_2,2\}:a+1 \leq c_2 \leq n-1 \right\}, \quad a < b - 1$$
$$\left\{ \left( \{c_1,1\}:1 \leq c_1 \leq b-2 \right) \cup \{c_2,2\}:a+1 \leq c_2 \leq n-1 \right\}, \quad a = b - 1$$

Moreover, by a careful inspection, we can conclude the
following theorem 1 for the transition probability matrix
of $Y_p$.

**Theorem 1:** The (one-step) transition probability
matrix $P = (p_{i,d})$, where $c$ and $d \in \tilde{E}_{(n,a,b)}$, of the DTMC
$Y_p$ is such that for $c \neq (0,1)$,

$$p_{i,d} = \begin{cases} d_{i-1}^{(b)} & c_2 = d, \quad c_2 = d, \quad \text{and } (b-1, c_2-1) \leq d_i \leq b-2 \\ d_{i} & \text{otherwise} \\ 0 & \text{otherwise} \end{cases}$$

(12)

with $r_{i,d}^{(b)}$ defined in Lemma 1. Moreover,

$$p_{i,b-1}^{(b)} = \begin{cases} f_{i,b-1}^{(b)} & d_i < b-1 \\ f_{i,b-1}^{(b)} + f_{i,b-1}^{(b)} & d_i = b-1 = a \\ 0 & \text{otherwise} \end{cases}$$

(13)

and

$$p_{i,b-1}^{(b)} = \begin{cases} \sum_{i=0}^{b-i-1} f_{i,b-1}^{(b)} & d_i < b-1 \\ \sum_{i=1}^{b-i-1} f_{i,b-1}^{(b)} + f_{i,b-1}^{(b)} & b-1 \leq d_i < b-1 \\ \sum_{i=1}^{b-i-1} f_{i,b-1}^{(b)} + \sum_{i=1}^{b-i-1} f_{i,b-1}^{(b)} & d_i = b-1 = a \\ 0 & \text{otherwise} \end{cases}$$

(14)

with $x^+ = \max(x,0)$ and $x \wedge y = \min(x,y)$.

4. CONTINUOUS TIME STATE IN OSCILLATING SYSTEMS

In this section, we characterize the limit distribution of the
continuous time state process for the type I and type II
$M_2^{[x]} / G_1^* - G_2^* / 1 / n(a,b)$ systems, i.e., the limit
distribution $Y^c$.

To begin, we assume that $\tilde{S}_j(A)$ denotes a random
variable, whose distribution is the distribution of the
duration of a customer service time, $S$, with distribution
function $A$ given that $l$ customers arrive to the system
during this customer service time. Furthermore, let $\tilde{S}_j, 1 \leq j \leq l$,
denote random variables with the same distribution as the accumulated service time until the first
epoch at which \( j \) or more customer arrivals take place, given that exactly \( l \) customers arrive until the first moment at which \( j \) or more arrivals have occurred in a service period with a distribution function \( A_i \).

The following lemma shows how absolute moments of the conditional random variables \( \overline{S}_i(A) \) and \( \overline{S}^k_i \) may be computed.

**Lemma 2:** The absolute moment of order \( k \in N_+ \), of conditional random variables \( \overline{S}_i(A) \) and \( \overline{S}^k_i \), satisfies

\[
r_i(A)E[\overline{S}^k_i(A)] = \sum_{j=0}^{\infty} \left( \frac{j + k}{j!} \right) \lambda^j \alpha_{j,i}(A) f_i^{(j)}(A)
\]

for \( l \in N_+ \), and

\[
\sum_{l=1}^{\infty} r_l(A)E[\overline{S}^k_i(A)] = E[S^k_i(A)] - \sum_{l=0}^{n-1} \frac{(k + j)!}{j!} \alpha_{j,i}(A) f_i^{(j)}(A)
\]

moreover,

\[
q_{\lambda,i}(A)E[\overline{S}^k_i(A)] = \sum_{m=0}^{\infty} \frac{m + k}{m!} \alpha_{m,i}(A) \sum_{r=0}^{m} f_i^{(r)}(A)
\]

**Proof:** Let \( G \) denote the number of customer arrivals in duration of service a customer. For \( k \in N_+ \) and \( l \in N_+ \), we have:

\[
r_i(A)E[\overline{S}^k_i(A)] = E\left[ S^k_i(A) 1_{(G=l)} \right] = \int_{\mathbb{R}^+} u^k \sum_{j=0}^{\infty} \frac{e^{-\lambda u} \lambda^j}{j!} f_i^{(j)}(A) (du)
\]

\[
= \sum_{j=0}^{\infty} \left( \frac{j + k}{j!} \right) \lambda^j \alpha_{j,i}(A) f_i^{(j)}(A)
\]

Finally, equation (16) follows from equation (15) since

\[
\sum_{l=1}^{\infty} r_l(A)E[\overline{S}^k_i(A)] = E[S^k_i(A)] - \sum_{l=0}^{n-1} \frac{(k + j)!}{j!} \alpha_{j,i}(A) f_i^{(j)}(A)
\]

by taking into account that

\[
E[S^k_i(A)] = \sum_{l=0}^{\infty} r_l(A)E[\overline{S}^k_i(A)]
\]

We now address the computation of \( E[\overline{S}^k_i(A)] \), which goes as follows:

\[
q_{\lambda,i}(A)E[\overline{S}^k_i(A)] = \int_{\mathbb{R}^+} u^k \sum_{m=0}^{\infty} \frac{e^{-\lambda u} \lambda^m}{m!} \sum_{r=0}^{m} f_i^{(r)}(A) (du)
\]

\[
= \lambda^k \sum_{m=0}^{\infty} \frac{(m + k)!}{m!} \sum_{r=0}^{m} f_i^{(r)}(A)
\]

which leads to (17), in view of (2).

We use the above lemma to address the limit distribution \( Y \). We first note that the state process \( Y \) is a M/G/1 service system with state space \( E^{(n,a,b)} \) associated with the time sequence \( (T_j)_{j \in A} \) of post-customer departure epochs. Therefore, using Kulkarni [19] (Theorem 9.30), we conclude that the limit probability vector of \( Y \),

\[
p = (p_d)_{d \in E^{(n,a,b)}} ,
\]

given by the following function of the limit post-customer departure state probability vector,

\[
\pi = (\pi_e)_{e \in E^{(n,a,b)}},
\]

\[
p_d = \sum_{e \in E^{(n,a,b)}} \pi_e \phi_d,
\]

with \( d \in E^{(n,a,b)} \), where:

- \( \phi_d \) denotes the mean time elapsed between two consecutive service completions conditioned on the state of the system after the first of these service completions being \( c \), i.e.,

\[
\varphi_d = E[T_{n+1} - T_1 | Y(T) = c]
\]

for \( c \in E^{(n,a,b)} \).

- \( \phi_{cd} \) denotes the expected sojourn time of \( Y \) in state \( d \) in-between two consecutive service completions conditioned on the state of the system after the first of these service completions being \( c \), i.e.,

\[
\varphi_{cd} = E[Y(T_{n+1}) - Y(T_1) | Y(T) = c]
\]

for \( c \in E^{(n,a,b)} \), \( d \in E^{(n,a,b)} \).

**Theorem 2:** The mean time elapsed between two consecutive service completions conditioned on the state of the system after the first of these service completions being \( c \), \( \varphi_c \), obtains in type I \( M^{[x]} / G_1 - G_2 / 1 / n/(a,b) \) systems as:

\[
\varphi_c = \left\{ \begin{array}{ll}
\frac{1}{\mu_1} & c = (0,1) \text{ and } b = 1 \\
\frac{1}{\mu_1} + \frac{1}{\mu_2} & c = (0,1) \text{ and } b > 1 \\
\frac{1}{\mu_1} & c_1 = 1 \text{ and } c_1 > 0 \\
\frac{1}{\mu_2} & c_1 = 2 \\
\end{array} \right.
\]

and, in type II \( M^{[x]} / G_1 - G_2 / 1 / n/(a,b) \) systems

\[
\varphi_c = \left\{ \begin{array}{ll}
\frac{1}{\mu_1} & c_1 = 2 \\
\frac{1}{\mu_2} + \frac{1}{\mu_1} & c_1 = 1 \text{ and } c_1 \neq 0 \\
\frac{1}{\mu_1} + \frac{1}{\mu_2} & c = (0,1)
\end{array} \right.
\]

**Proof:** We first note that equation (19) for type I oscillating systems follow similarly to the case of regular systems taking into account that the duration of a service
initiated with the system in phase \( \alpha \) has expected value \( \lambda/\mu_2 \), \( i = 1,2 \).

Suppose now that the oscillating system is of type II.

The first branch of (20) follows from the fact that a service time initiated with the system in phase 2 has distribution function \( A_2 \) with mean \( \lambda/\mu_2 \). In addition, if \( c = (c_1,1), c_i > 0 \), then \( \varphi_c \) is the mean duration of a service time initiated in state \( c \), for which conditioning on the number of customers that arrive to the system during the first service time, we obtain

\[
\varphi_c = \sum_{i=0}^{b-c-1} r_i(A_i)E[S_i(A_i)] + \sum_{i=b-c}^{a_1-1} q_{b-c-i}(A_i) \left( E[S_{b-c-i}] + \frac{1}{\mu_2} \right). \tag{21}
\]

Now, taking into account Lemma 2, we have

\[
\sum_{i=0}^{b-c-1} r_i(A_i)E[S_i(A_i)] = \sum_{i=0}^{b-c-1} \sum_{j=0}^{1} \frac{1}{\lambda} f_{i-j} = \sum_{i=0}^{b-c-1} \sum_{j=0}^{1} \frac{1}{\lambda} f_{i-j}^{(i-1)}. \tag{22}
\]

Similarly, taking into account equation (17), in Lemma 2, and (11), we have

\[
q_{b-c-i}(A_i)E[S_{b-c-i}] = \frac{1}{\lambda} \sum_{i=0}^{b-c-1} \sum_{j=0}^{1} \alpha_i(A_i) \sum_{u=c-i}^{b-c-1} f_u = \alpha_i(A_i) f_{m-a},
\]

for \( m \geq b - c_1 \), so that

\[
\sum_{i=b-1}^{a} q_{b-c-i}(A_i)E[S_{b-c-i}] = \frac{1}{\lambda} \sum_{i=0}^{b-c-1} \sum_{j=0}^{1} \alpha_i(A_i) \sum_{u=c-i}^{b-c-1} f_u = \alpha_i(A_i) f_{m-a}. \tag{23}
\]

Now, the validation of the second branch of (20) follows from (21), by taking into account (22) and (23) and the fact that

\[
\sum_{i=b-1}^{a} q_{b-c-i}(A_i) = \sum_{i=b-1}^{a} r_i(A_i).
\]

Finally, the third branch of (20) follows from the facts already established by conditioning on the size of the first batch arriving after a service completion that leaves the system empty, taking into account that the mean waiting time for this batch to arrive to the system is equal to \( 1/\lambda \).

By conditioning on the number of customer arrivals in the first service that takes place after a service completion that leaves the system in state \( c \), we conclude the following result.

**Theorem 3:** In \( M^{[2]}/G_i - G_i/1/1/n/(a,b) \) systems,

\[
\phi_{d_1} = 0, \text{ if } d_1 \leq c_1. \text{ In type I and type II systems,}
\]

\[
\phi_{d_1} = \begin{cases} 0 & d_1 \leq c_1, d_1 = 1 \\ \sum_{i=0}^{n-1} \tau_i(A_i) & c_i \leq d_i \leq n - 1 \\ \sum_{i=n}^{d_i} \tau_i(A_i) & d_i = n \end{cases}
\]

(24)

In turn, in type I systems,

\[
\phi_{d_1} = \begin{cases} 0 & d_1 \leq c_1, d_1 = 1 \\ \sum_{i=0}^{n-1} \tau_i(A_i) & d_i = n \end{cases}
\]

and in type II systems,

\[
\phi_{d_1} = \begin{cases} 0 & d_1 \leq c_1, d_1 = 1 \\ \sum_{i=0}^{n-1} \tau_i(A_i) & d_i = n \end{cases}
\]

(25)

If \( c_1 > 0 \). Moreover,

\[
\phi_{d_1} = \begin{cases} 0 & d_1 \leq c_1 \\ \sum_{i=0}^{n-1} \tau_i(A_i) & d_i = n \end{cases}
\]

(26)

in type I and type II systems.

5. ALGORITHMIC ANALYSIS

We summarize the obtained results in previous sections as a procedure to calculate the limit distributions of the post-customer departure state and the continuous time state in type I and type II \( M^{[2]}/G_i - G_i/1/1/n/(a,b) \) systems by the algorithm given in Figure 1.

This algorithm requires as input the mixed-Poisson probabilities \( (\alpha_i(A_i))_{i=1,2} \) and \( (\alpha_i(A_i))_{i=1,2} \), along with the batch size probabilities \( f_i \). The algorithm consists of eleven steps, with the first six steps including the computation of auxiliary quantities that are used in steps 7-11. The computation of the limit probability vector of the post-customer departure state \( \pi = (\pi_i) \) is done in Step 8, where \( \pi \) denotes a vector of ones. The computation of the limit probability vector of the continuous time state \( p = (p_i) \), is done in Step 11 and requires the quantities computed in steps 8-10. We note that in the considered oscillating systems, the lower and upper boundaries (respectively, \( a \) and \( b \)) are smaller or equal to \( n \).
Algorithm

Input: \( n, a, b, \lambda, \mu_i, \mu_j \), \( f_i(A) \) \( \alpha_i(A), \alpha_j(A) \) \( \gamma_i(A), \gamma_j(A) \) \( \phi \) \( \rho \) \( \sigma \) \( \tau \) \( \pi \)

1. Compute \( f_i(A) \) using (1).
2. Compute \( \gamma_i(A), \gamma_j(A) \) using (9) and (10).
3. Compute \( \phi_i(A), \phi_j(A) \) using (7) if the system is of type II.
4. Compute \( \tau_i(A), \tau_j(A) \) using (2).
5. Compute \( \phi_i(A), \phi_j(A) \) using (5) if the system is of type II.
6. Compute \( \gamma_i(A), \gamma_j(A) \) using (11).
7. Compute \( P_i(A) \) using (12)-(14).
8. Compute \( \pi \) such that \( \pi = \pi P \) and \( \pi 1 = 1 \).
9. Compute \( \phi_i(A), \phi_j(A) \) using (19) if the system is of type II.
10. Compute \( \phi_i(A), \phi_j(A) \) using (24)-(27).
11. Compute \( p_i(A) \) using (18).

Output: \( \pi = (\pi_i)_{i \leq n} \) and \( p = (p_i)_{i \in E^{\nu \times \nu}} \).

Figure 1: Algorithm to compute the limit distributions of the post-customer departure state and the continuous time state in type I and type II \( M^{[\nu]}/G_i/G_{\nu}/I/n \) system.

6. Numerical Results

In this section, we use the result proposed in the previous sections to solve several oscillating \( M^{[\nu]} / G_i / I/n \) systems and illustrate the sensitivity of their associated limit distributions and performance measures with respect to batch size and service time distributions.

Specifically, to evaluate the influence of the batch size distribution we consider the following batch size distributions with common mean \( \nu \): deterministic - the constant \( \nu \), \( D(\nu) \): geometric with success probability \( 1/\nu \), \( Geo(1/\nu) \); shifted binomial - a binomial with \( m \) trials and success probability \( (\nu-1)/m \) added of one unit, \( 1+B(m,\nu-1)/m \) and, discrete uniform on the set \{1,2,...,2\nu-1\}, \( Unif(1,2\nu-1) \).

The service time distributions presented in this section have the following parameterization with positive mean \( \mu^1 \): deterministic with value \( \mu^1 \), \( D(\mu^1) \): exponential with rate \( \mu \), \( E(k,\nu) \): Erlang with \( k \) phases, \( E_k(k,\mu) \): and, \( P(x\nu,k,\mu) \): Pareto with parameters \((\beta,k)\) with \( \beta > 1 \) and \( k = (\beta - 1)/\beta \mu \).

We let also \( \pi = (\pi_i)_{i \in E^{\nu \times \nu}} \) denote the limit probability vector of the number of customers in the system at post-customer departures, and \( p_i = (p_i)_{i \in E^{\nu \times \nu}} \) denote the limit probability vector of the number of customers in the system in continuous time, so that

\[
\begin{align*}
\pi_i &= \begin{cases} 
\pi_i(a) & 0 \leq i \leq a \\
\pi_i(a) + \pi_i(b) & a + 1 \leq i \leq b - 1 \\
\pi_i(b) & b \leq i < n 
\end{cases} \\
p_i &= \begin{cases} 
p_i(a) & 0 \leq i \leq a \\
P_i(a) + P_i(b) & a + 1 \leq i \leq b - 1 \\
P_i(b) & b \leq i < n 
\end{cases}
\end{align*}
\]

First, to illustrate the methodology, we present in tables 1, 2 and 3 the limit probability vector of the number of customers at post-customer departures, \( \pi = (\pi_i)_{i \in E^{\nu \times \nu}} \), and in continuous time, \( p_i = (p_i)_{i \in E^{\nu \times \nu}} \), of regular and type I and type II oscillating \( M^{[\nu]} / G_i / I/n \) systems.

</table>
Tables 1 and 2 show how the number of customers in the system evolves in regular $M^{Geo(2/3)}/D(2/3)/1/20$, $M^{Geo(2/3)}/D(1.09)/1/20$ and $M^{Geo(2/3)}/D(4/3)/1/20$ systems and in type I $M^{Geo(2/3)}/D(2/3)/1/20/(7,11)$ systems with customer batch arrival rate $\lambda = 2/3$. The second regular system considered has the same mean service rate of the overall mean service rate in the oscillating system, i.e.,

$$
\mu^{-1} = \frac{4}{3} \sum_{i=0}^{\infty} p(i, 1) + \frac{2}{3} \sum_{i=1}^{\infty} p(i, 2) = 1.09
$$

where, for instance, $\sum_{i=0}^{\infty} p(i, 1)$ is the proportion of time the oscillating system is in phase 1.

In Table 3 we can compare type I and type II $M^{Geo(1/4)}/D(2) - D(5/4)/1/20/(7,11)$ systems. The results show that the limit probability vectors of the number of customer at post-customer departure and in continuous time are similar for the compared type I and type II oscillating systems and the barriers of oscillating systems has a big effect on the number of customers in the system.

We next proceed to illustrate the sensitivity of performance measures associated with oscillating type II $M^{[x]}/G/1/n$ systems with respect to batch size and service time distributions.

In Figure 2 we consider type II $M^{[3]}/M(0.6) - M(1.1)/1/20$ systems with service rate 0.6 in phase 1 and service rate 1.1 in phase 2. The figure shows how the mean number of customers in the system depends on the batch size distribution and how it evolves as a function of the lower and upper barriers.

Figure 3 shows how the mean number of customers in the system evolves as the lower and upper barriers increase, for several service time distributions. The systems considered have deterministic batch size distribution with mean 3, and batch arrival rate 1/3. The service time distributions have service rate 0.6 in phase 1 and service rate 1.1 in phase 2. From figures 2 and 3 we can conclude that the batch size and service time distributions influence the mean number of customers in the system.
Figure 2: Mean number of customers in type II $M^{[x_1]}/M(0.6)\sim M(1.1)/1/20/(a,b)$ systems with a batch arrival rate $1/3$, for several batch size distributions with mean 3.

Figure 3: Mean number of customers in type II $M^{[x_3]}/G(0.6)\sim G(1.1)/1/20/(a,b)$ systems with batch arrival rate $1/3$, for several batch size distributions.

Figure 4: Mean number of customers in type II $M^{[x_3]}/G(0.6)\sim G(1.1)/1/20/(8,15)$ systems with unit customer arrival rate and shifted binomial batch size distribution on the first one, and geometric batch size distribution on the next one, as a function of the mean batch size for several service time distributions.

Figure 4 gives the mean number of customers in type II $M^{[x_3]}/G(0.6)\sim G(1.1)/1/20/(8,15)$ systems with customer arrival rate $(\lambda_f)$ kept fixed equal to the unit; and shifted binomial batch size distribution on the left hand-side, and geometric batch size distribution on the right hand-side. We observe that for a given service time distribution, the mean number of customers in the system depends on the both batch size distribution and its mean.

7. CONCLUSION

We addressed oscillating batch arrival $M^{[x_1]}/G/1$ systems with finite capacity $n$ and computed the limit distribution of the both state of the system at post-customer departure epochs and the state of the system in continuous time. We also explained how the computation of the limit distribution of the state of the system may be implemented for the considered system by represented an algorithm. The numerical results showed that the limit probability vectors of the number of customer at post-customer departure and in continuous time are similar for type I and type II the oscillating systems and the barriers of oscillating systems has a big effect on the number of customers in the system. Also, the batch size and service time distributions influence the mean number of customers in the system.
