Abstract
It has been found that appropriate probiotic applications increased growth performance and disease resistance in shrimp. *Bacillus subtilis* has been suggested as a potent probiotic in improving growth performance and enhancing immune response in white shrimp, *Litopenaeus vannamei*. The aim of this work was to evaluate the possible effect of *B. subtilis* administration on the meat fatty acid profile of white shrimp, *L. vannamei*. Two groups of shrimps received *B. subtilis* strains L10 and G1 from the *B. subtilis*-supplemented feed (10⁵ and 10⁸ CFU g⁻¹) while two other groups received it from the rearing water (10⁵ and 10⁸ CFU ml⁻¹). One group received no *B. subtilis* and served as control. According to the results, there was no significant difference between the muscle fatty acid profiles of shrimps administrated by probiotic and control group. This study showed that *B. subtilis* administration, in either diets or water, did not have any negative effect on fatty acid profiles of *L. vannamei* meat.

Introduction

Probiotics are defined as a live microbial supplement which beneficially affects the host animal by improving its microbial balance (Gram et al., 1999). It has been found that appropriate probiotic application would increase growth performance and disease resistance in shrimp (Castex et al., 2008, van Hai and Fotedar, 2010). A variety of microbial species have been successfully applied as probiotics in shrimp including species of Bacillus (Balcázar and Rojas-Luna, 2007), Lactobacillus (Chiu et al., 2007) and Pseudomonas (Alavandi et al., 2004).

Several mechanisms of action of probiotics have been found in human and terrestrial animals including prevention of overgrowth of potentially pathogenic micro-organisms, stimulation of the intestinal immune defense system, participation in the regulation of intestinal functions such as mucus utilization and nutrient absorption, production of nutrients and micronutrients of special importance such as fatty acids and vitamins (see the reviews by Bengmark, 1996 and Fuller, 1989). Some of the above mentioned functions have also been found in shrimp including production of inhibitory compounds in the intestine of the host as well as acting as an immune stimulant (see the review by Verschuere et al., 2000). However, there is no unambiguous experimental data on the production of nutrients, such as fatty acids in the intestine of aquatic animals administrated by probiotics.

It has been shown that administration of Lactobacillus amylovorus and Enterococcus faecium mixed culture increases monounsaturated (MUFA) and polyunsaturated fatty acids (PUFA) in pig meat (Ross et al., 2012). On the other hand, there is evidence that supplementation of commercial probiotic containing Saccharomyces cerevisiae and L. acidophilus reduces the 18:3n-3 concentration in goat plasma (Paengkoum and Yong, 2009). Dietary supplementation of probiotics has been also found to play an important role in altering the lipid metabolism of chickens and to affect their egg fatty acid profile (Mikulski et al., 2012). As far as we know, there is currently no published information about the effect of probiotic administration on the meat fatty acid profile of fish and crustaceans.

B. subtilis has been suggested as a potent probiotic in improving growth performance and enhancing immune response in white shrimp, L. vannamei (Zokaeifar et al., 2012b). Shrimp are regarded as the world’s most popular shellfish and considered as a good source of long chain n-3 PUFA (Turan et al., 2011). Therefore, any probiotic administration is needed to be monitored to prevent n-3 PUFA reduction in their meat. Any dietary manipulation and/or probiotic administration that change shrimp fatty acid profile may affect its nutritional value for final human consumption. The aim of the present study was to evaluate the possible effect of B.
subtilis administration on the meat fatty acid profile of white shrimp, L. vannamei.

Materials and Methods
Bacterial strains and Culture Conditions
B. subtilis strains L10 and G1 were isolated and identified from fermented pickles (Zokaeifar et al., 2012a), and used as probiotics. Probiotic strains were kept at -20 °C in Luria-Bertani broth (LB; Difco) containing 15% v/v sterile glycerol. Cultures were further activated by growing in LB broth at 30°C for 48 h as explained by Zokaeifar et al. (2012b).

Experimental Conditions
Pathogen-free L. vannamei juveniles of an initial weight of 0.70 ± 0.10 g (mean ± SD) were obtained from the Marine Science Research Station and Biology Field Station, University Putra Malaysia, and the experiment was conducted at the same place. The shrimp were randomly distributed into 10 fiberglass tanks containing 500 l seawater with the stocking density of 100 shrimps per tank and acclimated for 3 days prior to start of the growout experiment.

Two groups of shrimp received B. subtilis from the B. subtilis-supplemented feed while two other groups received this from the rearing water. For the feed groups, a mixture of B. subtilis strains L10 and G1 were sprayed over a commercial vannamei feed (Blanca, Charoen Pokphand Malaysia; crude protein 35%; crude fat 5%) to give a final concentration of approximately 10^5 CFU g\(^{-1}\) (L10, 5 \times 10^4 and G1, 5 \times 10^4 CFU g\(^{-1}\)), named as FB5 and 10^8 CFU g\(^{-1}\) (L10, 5 \times 10^7 and G1, 5 \times 10^7 CFU g\(^{-1}\)), named as FB8. For the water groups, mixtures of B. subtilis strains L10 and G1 were added into the rearing water to give a final concentration of approximately 10^5 CFU ml\(^{-1}\) (L10, 5 \times 10^4 and G1, 5 \times 10^4 CFU ml\(^{-1}\)) named as WB5 and 10^8 CFU ml\(^{-1}\) (L10, 5 \times 10^7 and G1, 5 \times 10^7 CFU ml\(^{-1}\)) named as WB8. One group served as the control and received probiotics from neither food nor rearing water. Both water groups as well as control group were fed un-supplemented commercial feed. The experiment was conducted in duplicate for 8 weeks. Feed and rearing water supplementation procedures were done twice a week. Shrimps were fed three times a day at 5% of body weight. At the end of the experiment, 5 shrimp from each replicate were randomly collected and their meat tissue was collected, lyophilized for 48 h and stored at -20 °C for further fatty acid analysis.

Water Supply and Analysis
The water was supplied directly from the sea. After series of treatment and filtration process, the salinity was reduced to 20 ppt using freshwater. Continuous aeration was provided and kept at a dissolved oxygen level of 5.0 ± 0.5 in each tank. Water quality was monitored every three days; pH was found between 7.4 and 8.6 and temperature ranged between 27 and 29°C. The nitrite-N, nitrate-N and ammonia-N were always within the acceptable ranges and found to be below 0.01, 4.0 and 1.1 mg l\(^{-1}\), respectively.
Fatty Acid Analysis
Lipid from lyophilized meat of shrimp was extracted with a chloroform:methanol (2:1 v:v) mixture, saponated by KOH and transesterified with methanolic boron trifluoride (Kamarudin et al., 2012). Fatty acid methyl esters (FAMEs) were then analyzed using a gas chromatograph (Agilent 7890A) equipped with a split/splitless injector (ratio 1:10), a fused silica capillary column (Supelco SP-2330: 30m × 0.25mm, 0.20 µm in film thickness) and a flame ionization detector (FID). High purity hydrogen was used as the carrier gas. Column temperature was set at 100°C for 2 minutes, increased to 170°C at a rate of 10°C/min, maintained for 2 minutes and increased again from 170 to 200°C at a rate of 7.5°C/min and maintained at 200°C for 20 minutes. Injector and detector temperature were 250 and 300°C, respectively. Fatty acids were identified by comparing the relative retention time with 37 component FAME mix standards (Supelco, Bellefonte PA, USA) and menhaden oil. The results were expressed as the area percentage of total identified fatty acids.

Statistical Analysis
Homogeneity of variances was tested using Levene’s test, and data identified as nonhomogeneous were subjected to arcsine transformation before statistical analysis. All experimental data were analyzed by one-way analysis of variance (ANOVA). Significantly different means were then elucidated using Duncan’s multiple range test. Statistical tests were conducted at 95 % confidence level using SPSS 19 for Windows (SPSS Inc., Chicago, IL, USA).

Results
The muscle fatty acid profiles of shrimp administrated with probiotic as well as the control group are shown in Table 1. The carbon chain length of the identified fatty acids was between 14C to 22C with 0–6 double bonds. The major fatty acids identified in the muscle of shrimps were C14:0, C16:0, C18:0, C18:1n-9, C18:2n-6, C20:4n-6 (arachidonic acid; ARA), C20:5n-3 (eicosapentaenoic acid; EPA) and C22:6n-3 (docosahexaenoic acid; DHA) while the most abundant fatty acids were found to be C16:0, C18:2n-6, C18:0, C18:1n-9, EPA and DHA, ranging from 83.5% to 85.8% of the total fatty acids in the muscle of L. vannamei. The latter fatty acids except for C18:2n-6 were found as the major constituents of fatty acid profiles in muscle of L. vannamei (Montano and Navarro, 1996). The high amount of C18:2n-6 in the muscle of all examined groups in this study was most probably due to high ratio of this fatty acid in their commercial diet. It has been shown that high inclusion of C18:2n-6 in the diet of L. vannamei increases the percentage of this fatty acid in their body tissues (Zhou et al., 2007).
Table 1: Fatty acid profile (% of total fatty acid) of meat of *Litopenaeus vannamei* cultured with probiotics *Bacillus subtilis*, strains L10 and G1 or fed with *B. Subtilis*-supplemented diet.

Values reported are mean ± SE (n=10).

The distribution pattern of the fatty acids sum in total fatty acids within shrimp muscle was: PUFA > saturated fatty acid (SFA) > MUFA (Table 2). A similar distribution pattern has been found for *Macrobachium rosenbergii* (PUFA: 43% > SFA: 35% > MUFA: 22% of total fatty acid) (Bragagnolo and Rodriguez-Amaya, 2001), *Penaeus monodon* (PUFA: 44.3% > SFA: 35.4% > MUFA: 20.3% of total fatty acid) and *L. vannamei* (PUFA: 42.2% > SFA: 35.8% > MUFA: 22% of total fatty acid) (Sriket et al., 2007). However, this pattern can be extremely influenced by diet, season and geographical zone (Soriguer et al., 1997; Yanar, 2005; Tziouveli and Smith, 2012).
Table 2: Sums of SFA, MUFA and PUFA (% of total fatty acid) in the meat of *Litopenaeus vannamei* cultured with probiotics *Bacillus subtilis*, strains L10 and G1 or fed with *B. subtilis*-supplemented diet.

Discussion

In the current experiment, there was no effect of probiotics, added either to feed or rearing water, on the individual fatty acid or sum of the fatty acids in the muscle of *L. vannamei*, compared to the control group. Recently, extensive consideration has been given to the potential of probiotics in changing lipid metabolism in terrestrial animals. However, most studies have focused primarily on serum fatty acid alteration imposed by probiotic administration (Ashayerizadeh et al., 2009, Paengkoum and Yong, 2009); and information about the effect of probiotics in altering meat fatty acid profile is still scarce. Ross et al., 2012 reported that inclusion of *L. amylovorus* and *Enterococcus faecium* mixed culture increases total MUFA, C18:2n-6 and C18:3n-3 in pigmeat significantly. This could be due to the ability of some bacteria to produce conjugated linoleic acid and affect host metabolism and fat composition in liver and adipose tissue in different animal species (Wall et al., 2012). According to our results, *B. subtilis* strains L10 and G1 should not be able to produce fatty acid in shrimp intestine in a way that affects tissue fatty acid composition. On the other hand, probiotic administration has a potential to facilitate biohydrogenation of unsaturated fatty acids to more saturated ones and reduce the unsaturated FA to saturated FA ratio in the body of ruminants (Paengkoum and Yong, 2009), which is not a desirable alteration for human health. Such a negative effect of probiotic has not been observed in broiler chicken. Král et al. (2013) reported that there is no significant difference between SFA, MUFA and PUFA amounts in the meat of broiler chicken fed with *B. subtilis*-supplemented diet and those fed diet with no probiotic supplementation. Our results also showed that supplementation of shrimp feed with *B. subtilis* did not increase SFA amount in their muscle. The PUFA/SFA ratios in the muscle of all shrimps ranged from 1.00 to 1.10 without any significant difference.
Saturated and trans fatty acids increase cardiovascular risk, while both n-6 and n-3 PUFAs have been associated with lower cardiovascular risk (Erkkila et al., 2008). Meanwhile, the n-3/n-6 ratio is known as an important factor in human diet and many health disorders are linked with high intake of n-6 fatty acids through diet (Steffens, 1997). The n-3/n-6 ratios in our study were found to be between 0.79 and 0.92 and there was no significant difference between different treatments.

Results of this study revealed that B. subtilis strains L10 and G1 administration, either through the rearing water or by feed supplementation, did not change the fatty acid profiles of total lipid content of muscle of L. vannamei. Therefore, B. subtilis should not be able to produce fatty acids in shrimp intestine in a way that affects their tissue fatty acid composition. Moreover, B. subtilis administration does not have any negative effect on fatty acid profiles of L. vannamei meat.
