Abstract:

Background: Fluorine is an essential micronutrient for human health, serving to strengthen the apatite matrix of skeletal tissues and teeth. In regions where the fluoride (F−) concentration of water is naturally low (<0.5 mg/l), some communities have chosen to add this constituent to their drinking water to strengthen teeth and to minimize cavities. The aim of this study was to determine fluoride concentration in drinking water in Shahroud city at the northern part of Iran as well as determination of DMF value in 7 year old children, for a duration of 6 years.

Materials and Methods: In this descriptive study, 138 students aged 7 were chosen randomly from Shahroud schools and were followed up for a duration of 6 years (2004-2009). They were examined by a dentist for determining the numbers of decayed, missing and filled permanent teeth. Also 120 samples were taken from drinking water in the city and Ion-selective method was used for measuring fluoride concentration. Determination of both DMF index and fluoride mean concentration was repeated for six years from 2004 to 2009.

Results: Fluoride concentrations were between 0.45 to 0.75 mg/L and DMF index was between 3.18 to 3.81. There was a significant difference between both DMF index and fluoride mean concentrations in different years.

Conclusions: DMF index obtained in our study was higher than the index reported for the whole country (1.2-2.6mg/L).

Key words : DMF, Drinking water, Fluoride concentration, School children.

Introduction

Fluorine is found in the environment as fluorides, mainly because it is the most electronegative and reactive of all chemical elements. All natural waters have fluoride ranging from trace levels to several dozen mg/l.[1-2] Fluorine is an essential micronutrient for human health, serving to strengthen the apatite matrix of skeletal tissues and teeth. In regions where the fluoride (F−) concentration of water is naturally low (<0.5 mg/l), some communities have chosen to add this constituent to their drinking water to strengthen teeth and to minimize cavities [1]. On the other hand, high F− (>1.5 mg/l) results in dental and skeletal fluorosis, renal and neuronal disorders and myopathy [3]. Endemic fluorosis develops widely in many areas of the world, such as China [4], India [5-7] and Mexico [8]. In Iran, the occurrence of high F− groundwater has been reported in Dashtestan [9].
Exceptionally higher values were also found such as flouride concentration in the water of some lakes in Kenya where the content of flouride is over 2000 mg/l [2]. It is generally accepted that flouride is an essential component of all diets and that most of the body requirements are obtained from drinking water. A small fraction of this flouride accumulates on the teeth and bones and most of it is eliminated in urine and sweat. An excessive concentration of flouride can cause fluorosis [3]. Water flouridation at the 1.0 mg/L level is supposed to be beneficial for caries prevention although excessive ingestion of flouride during maturation could cause dental fluorosis.

There is a big controversy on the usefulness of flouride in protecting tooth decay. In 1984 , world health organization recommended keeping the concentration of flouride in range of 0.5-1.5 mg/L in order to prevent dental caries especially in children [13-14]. It is known that relative effectiveness of systematic flouridation has diminished over time since the 1990s [10-15]. The aim of this study was to determine flouride concentration in drinking water in Shahroud city (northern Iran) and also to determine DMF index between school age students in a duration of six years from 2004 to 2009.

Materials and methods

This cross sectional study was carried out in Shahroud city in Northern part of Iran on drinking water as well as measuring DMF among 7 year old school children (boys) from 2004 to 2009. A sample size of students was estimated as 138 subjects based on: prevalence=20%, α=0.05 and precision (d=0.07). The subjects were selected randomly from the list of all the 7 year old school children. A study questionnaire was completed. The data analysis was performed in SPSS (version 11.5) using one way ANOVA test.

120 samples were taken from the drinking water in Shahroud city and the level of flouride concentration was determined for each year. Flouride concentration was determined electrochemically, using approved USEPA ion-selective method (method 3402) [13] the electrode used was a flouride/combination flouride elector-orion 96-09 which was coupled to an Orion 420A electrometer (pH meter). Standards were prepared from a stock solution (100mg/l) of sodium flouride. This is applicable to the measurement of flouride in drinking water, surface water and saline waters in a range of concentration from 0.1 up to 1000 mg/l.

Figure 1. Location of Shahroud in Iran

Further, 138 students, aged 7 years old, were randomly chosen and examined by a dentist in schools for determining the numbers of decayed, missing and filled permanent teeth. Measuring both flouride concentrations and DMF index were repeated for six years as the sample of students was followed up. In fact, the students were 8, 9, 10, 11 and 12 years old in years: 2004, 2005, 2006, 2007, 2008 and 2009 respectively. Locations of the samples where the water were taken during the study were not changed. Samples were collected in clean flouride free plastic bottles directly from 120 sites. Trace grade nitric acid was added to preserve the samples. The
samples were then stored at approximately 5 °C and the amount of fluoride was determined in the laboratory of school of health.

**Results**

The mean concentrations of fluoride in the water samples are shown in table 1. As it is presented, the range of fluoride level during the six years of study was between 0.45 and 0.75 mg/l. The lowest mean fluoride level was 0.45 mg/l for 2006 and the highest was 0.75 mg/l for 2009. The mean fluoride levels were approximately the same for winter and summer in all of 120 locations that samples were collected. A one way ANOVA was conducted to compare fluoride level means in years: 2004, 2005, 2006, 2007, 2008 and 2009. There was a significant effect for time, Wilks’ Lambda=0.05, p<0.001. No fluoridation program has been set for this city up to day. The numbers of decayed, missed and filled tooth and mean values of DMF index and mean values of fluoride during the years of study have been shown in table 1.

Results showed that values of DMF index in our study were higher than the national average of DMF index. DMF index for Iran on the basis of world health organization reports is in range of 1.2 up to 2.4. Value of DMF index has increased with the increase of the student's age and the increasing trend of decayed teeth is more than increasing trends of missing and filled teeth. The numbers of decayed, missed and filled teeth over the study duration are compared in Figure2.

**Discussion**

Previous studies show that the DMF prevalence among students of Baboul town was reported as 2.98 ±1.98 in the 12-year-olds [16]. The DMF value was higher in girls than in boys. In another survey in Mashhad, the DMF was reported to be 2.32 ± 2.34 in
boys and 2.52 ± 2.12 in girls [10]. Majidi reported DMFT of 0.33 for boys 0.58 and for girls 0.087 [17]. The results of our study showed that as values of flouride increase, DMF index increases too, but this association is not significant. In places with low and optimal flouride concentration in drinking water the percentage of children with decayed teeth was different, but this difference was not statistically significant. The percentage of affected deciduous teeth was high in all places. In places with low flouride concentration this percentage was 4.2-12.7%, and in places with optimal concentration was reported to be 4-12%. The average value of DMF in all places is between 3.18-3.81. These results show that the optimal flouride concentration in drinking water decreases the incidence of tooth decay, but this difference was not significant. Our results showed that values of DMF index were higher than the national average. DMF index for Iran on the basis of world health organization reports is in range of 1.2 up to 2.4. 

Studies done in three communities of Iran showed that DMF index was 4.4, 6.0 and 5.0 in students aged 9 years-old in Tehran(16), Semnan and Village of Dibaj, respectively [17]. These values are higher than DMf index values for Shahroud city. A study in England [14] showed that DMF index was 2 in 2-year-old children. Also, a study done in Broken bow [15], showed that DMF index was 3.6. The mean concentrations of flouride in the water samples, during the six years of study was between 0.45 and 0.75 mg/l which is placed in low to middle level and, therefore flouride should be added to drinking water to increase flouride concentration to a minimum of 1 mg/L regarding the regional temperature (approximately 25 °C). A study in Spain [11] showed that flouride concentration was between 0.001-1.9 mg/l in village of Almaluez. In another study [19] flouride concentration in tap water in chile [19] was between 0.07-1.7 mg/L. Another study in Broken bow [9] showed that flouride level was low (<0.3 ppm). All the results of these studies show that the natural amount of flouride in drinking water are different all over the world.

Conclusions

Fluoride continues to be the cornerstone of dental caries prevention throughout the world, and there are a variety of sources of flouride that may contribute to the dietary intake of flouride. Even though Shahroud is considered as a non-endemic area for dental fluorosis according to its low concentration of flouride in drinking water, the children in our study presented epidemiological indicators of overexposure to flouride. Epidemiological indexes showed simultaneously high prevalences of caries. Because our knowledge is incomplete regarding the amount, duration, and timing of flouride ingestion which can result in dental fluorosis, further research is clearly needed before definitive recommendations can be made regarding the use of floridies, including the recommended dietary intake of flouride. Further longitudinal studies are also needed to determine the safe fluorine dose for Shahroud children, taking in account age, nutritional status, altitude, geographical location and weather among other factors.
