ABSTRACT

Purpose: This study was performed to investigate the incidence of thrombophilic gene mutations in repeated assisted reproductive technology (ART) failures. Methods: The prevalence of mutated genes in the patients with a history of three or more previous ART failures was compared with the patients with a history of successful pregnancy following ARTs. The study group included 70 patients, 34 with three or more previously failed ARTs (A) and control group consisted of 36 patients with successful pregnancy following ARTs (B). All patients were tested for the presence of mutated thrombophilic genes including factor V Leiden (FVL), Methylenetetrahydrofolate reductase (MTHFR) and Prothrombin (G20210A) using real-time polymerase chain reaction (RT-PCR). Results: Mutation of FVL gene was detected in 5.9% women of group A (2 of 34) compared with 2.8% women (1 of 36) of control group (P = 0.6). Mutation of MTHFR gene was found in 35.3% (12 cases) as compared with 50% (18 cases) of control (35.3% versus 50%; P = 0.23). Regarding Prothrombin, only control group had 5.6% mutation (P = 0.49). No significant differences were detected in the incidences of FVL, Prothrombin and MTHFR in the study group A compared with the control group B. Conclusion: The obtained results suggest that thrombophilia does not have a significant effect in ART failures.

Introduction

Infertility affects couples ranged from 3.5% to 16.7% in developed countries and from 6.9% to 9.3% in developing nations. There are many known causes such as tubal factor, unovulation, uterine abnormality, male factors as well as unexplained reasons which make infertile couples are not able to conceive naturally. Assisted reproductive technologies (ARTs) provide hopes for those couples; however the average pregnancy rate following ARTs despite transfers of good-quality embryos is 30-40% and the main cause might be an implantation failure. Association between inherited thrombophilia and unexplained infertility reported before. Both acquired and inherited thrombophilic gene mutations can be accepted as risk factors for recurrent pregnancy loss. However the effect of thrombophilia on implantation failure is a controversial issue and there are conflicting results about this observation. Findings regarding the positive effects of heparin therapy in women with recurrent IVF-embryo transfer (ET) failure and caring thrombophilic defect make association between thrombophilia and reproductive failure to be investigated further.

The present study was carried out to compare the prevalence of three thrombophilic gene mutations in patients with a history of three or more implantation failures with patients with successful pregnancy following ARTs (IVF/intracytoplasmic sperm injection (ICSI) – ET, IVF/ICSI-ET) cycles at a Fertility Centre of AL-Zahra Hospital of Tabriz University, Tabriz, Iran.

Materials and Methods

This study was carried out in the AL-Zahra Hospital, Fertility Centre of Tabriz University, Tabriz and Iran. Patients underwent IVF/ICSI-ET were contacted by phone and invited voluntarily without any cost to take part in this study and no intervention has been made to select patients. The percipients completed the consent form according to the Ethical Committee of Tabriz University of Medical Sciences. A total of 70 infertile women, aged 20-35, underwent ART cycles, based on
Results

Seventy infertile couples, divided into two groups of group A (with unsuccessful pregnancy) and group B, which their pregnancy verified by positive βHCG as well as clinical pregnancy proven using transvaginal ultrasonography, did not have statically significant differences regarding, age, a history of previous successful pregnancy, type of infertility treatment protocol, education; however BMI was significantly lower in group (B) with successful pregnancy (p=0.02) than that of the other group (A). The clinical characteristics of both groups are summarized in Table 1.

In both groups, mutations in three inherited thrombophilia genes: FVL, MTHFR and Prothrombin factor were investigated and the results of two groups were compared. Heterozygous Factor V Leiden mutation was found in two patients (5.9%) of group A and one patient (2.8%) of group B. There were no statically significant difference between these two groups (p = 0.6). Regarding MTHFR gene mutation, there were 12 cases (35.3%) in group A, two cases with homozygous genotypes and ten patients with heterozygous mutation and in group B, there were 18 cases (50%): 17 patients with heterozygous genotypes and 1 with homozygous mutation. There were no significant differences between these two groups (p = 0.23). Regarding Prothrombin gene mutation, there was not any case in group A, but in group B there were 2 cases (5.6%) with heterozygous genotype. There were no statically significant differences between the two groups (p = 0.49), as well (Figure 1).

Discussion

This paper describes the incidence of thrombophilic gene mutations of FVL, MTHFR and Prothrombin in patients with 3 or more IVF/ICSI-ET failure cycles compared with patients with successful IVF/ICSI-ET. The results revealed that there are no statically significant differences among women of two groups regarding these three mutated genes. In addition, in our study, the patient who had a combination of heterozygous MTHFR and FVL mutations and the other who had a combination of heterozygous MTHFR and Prothrombin mutations resulted in successful implantation. Moreover, two patients with homozygous MTHFR mutations had successful pregnancy.

These findings support the study carried out by Simur and coworkers25 and Martinelli and coworkers26 which reported no association between inherited thrombophilia and embryo implantation failures and Casadei and coworkers7 which mentioned it might be thrombophilia is not a risk factor for infertility; however several studies have shown an association between inherited thrombophilia and repeated IVF failures.12,19,21,26 The reason might be that there are other factors such as sample size and a familial history of prior thrombosis affecting implantation.

BMI: Body Mass Index

There are factors such as age, personal and/or family history of systemic diseases, number of antral follicles before stimulation, basal hormonal levels, previous pregnancy, endometrial thickness, embryo grading, ET technique and length and position of the uterus which influence success or failure rate of IVF/ICSI-ET, and perhaps affect the patients with thrombophilia, thus thrombophilia might not be a solely reason for the repeated ART failures.

Thrombophilia has been associated with poor obstetrical outcomes, local micro-thrombosis of maternal vessels at implantation site may affect syncytiotrophoblast invasion and might be resulted in implantation failure; however due to the development of intervillous space at the end of first trimester of gestation, it is possible that thrombophilia has less effects on implantation failure than that of other risk factors.

In summary, our findings suggest that there is not a relationship between solely thrombophilia and repeated implantation failures. However, implantation is a complex process and further research in large samples of infertile women might be needed.

Acknowledgments
The authors thank Fertility Centre of AL-Zahra Hospital of Tabriz University for their assistant with embryology work and Dr. Gojazadeh for statistical analysis. This research was supported by Women’s Reproductive Health Research Centre, Tabriz University of Medical Sciences.

Conflict of interest
The authors report no conflicts of interest.
