ABSTRACT

The patient with head trauma is a challenge for the emergency physician and for the neurosurgeon. Currently traumatic brain injury constitutes a public health problem. Knowledge of the various supportive therapeutic strategies in the pre-hospital and pre-operative stages is essential for optimal care. The immediate rapid infusion of large volumes of crystalloids to restore blood volume and blood pressure is now the standard treatment of patients with combined traumatic brain injury (TBI) and hemorrhagic shock (HS). The fluid in patients with brain trauma and especially in patients with brain injury is a critical issue. In this context we present a review of the literature about the history, physiology of current fluid preparations, and a discussion regarding the use of fluid therapy in traumatic brain injury and decompressive craniectomy.

Keywords: Brain trauma; Colloid solutions; Fluid resuscitation.

Please cite this paper as:

Introduction

Traumatic brain injury (TBI) is a major public health problem and a leading cause of death and disability [1]. It is frequently accompanied by haemorrhagic shock (HS) [2-5]. The mechanism for adverse outcome in patients with combined TBI and HS may be due in part to the secondary ischemic injury of already vulnerable brain following loss of cerebral auto-regulation and or to adverse effects of TBI itself on the normal compensatory response to HS [6]. Rapid infusion as quickly as possible of large volumes of crystalloids to restore blood volume and blood pressure is now the standard treatment for patients with combined TBI and HS [7,8]. Perioperative fluid administration is an important aspect of surgical care, but is often poorly understood [9-13], and continues to be an empirical exercise, with nagging questions about its efficacy and complications [14]. Fluid therapy (FT), as the name implies is a treatment with fluids [15]. The final goal of fluid management is to optimize the circulatory system to ensure the sufficient delivery of oxygen to organs [16]. FT is needed for the following conditions:

1. Normal maintenance;
2. Blood or fluid loss due to wounds, drains, induced diuresis etc;
3. Third space losses socalled fluid sequestration in tissue oedema or ileus;
4. Increased systemic requirements resulting from fever and hypermetabolic state.

TF should be tailored to match these requirements [17]. Intravenous (IV) fluids may be broadly classified
into colloid and crystalloid solutions. They have very different physical, chemical, and physiological characteristics. Colloid solutions can be natural (albumin) or synthetics (gelatins, dextrans, and hydroxyethyl starches).

Goal-directed fluid therapy (GDT) aimed at optimizing cardiac output and oxygen delivery has been shown to improve the outcome of high-risk surgical patients [18].

Most information presented herein is derived from the fluid management for the surgical patient in general, and those who were critically ill, such as trauma patients. Primary studies on preoperative fluid therapy for decompressive craniectomy (DC) are sparse.

The fluid management for patients undergoing elective major surgery, e.g., neurotrauma surgery, is controversial [19-21]. During the perioperative period, many pathophysiological changes occur that alter the normal efficiency of fluid homeostasis. Despite this, perioperative fluid prescription is often poor, being based on an insufficient knowledge of water and electrolyte requirements and distribution [22-25]. Perioperatively, crystalloids, colloids, and blood components are required to meet the ongoing losses and for maintaining cardiovascular stability to sustain adequate tissue perfusion [26,27].

Intravenous fluids maintain hydration while patients are unable to drink and replace losses that occur as a result of surgery [28]. Severity of illness, magnitude and duration of surgery, comorbidities and the host response to injury, influence the perioperative fluid needs. Although the principle goal of fluid administration is to maintain adequate tissue perfusion and the perils of over and under-resuscitation are well documented, there are no standards of care guiding for perioperative fluid administration [28]. The aim of this work is to review the current topics of fluid management in patients with traumatic brain injury and the candidates for decompressive craniectomy.

History of Modern Fluid Therapy

The intravenous fluid therapy (IVF) first gained importance in the treatment of cholera in the 1830s [29-34], with the reports of William Brooke O’Shaughnessy on his terminal cholera patients’ blood observations [29]. Their blood were thick and obscure, thus concluded that there was water deficit in those patients [31]. Aiming to replace the corporal fluid loss, the 0.9% physiologic saline solution was used for surgical patients. The perioperative use of IVF to compensate for the injurious effects of anaesthesia began in1880s. Clinical improvements were consequently noted, though the adverse effects of saline were observed. Thomas Latta was the first to administer intravenously water and salt solutions to dying patients with no favorable results [29,35]. The use of different mixes of water and salt in conjunction with the poor hygienic practices of those days, did not prove safe, thus the fluid therapy did not initially gain acceptance [15].

In 1880, Sidney Ringer observed the different protoplasmic activity of sodium, calcium, potassium and chloride salts, and introduced Ringer’s solution [15]. George Crile in 1899, using a hemorrhagic shock animal model, studied the solution and recommended it in warm form. War injuries during the First World War were treated with primitive saline and colloid solutions. The Gum arabic, a natural colloid from the Acacia senegal [1 tree used by W.C. Cannon, was a high point colloid [15].

In 1924, the intravenous “drip” was introduced by Rudolph Matas. In 1930, Hartmann and Senna in order to avoid the hyperchloremic acidosis resulting from the use of Ringer’s solutions [36], added sodium lactate, allowing sodium to be linked to the excessive chloride. This facilitated the lactate metabolism, thus, giving rise to the Hartman solution or Ringer-lactate. The work of Ringer, Hartmann, and others emphasized the importance of the composition of IV fluids and laid the foundations for the balanced solutions in use today [37]. During the Second World War, blood and plasma were massively administered, even in the battlefield, aimed at prolonging the lives of injured soldiers. In general, FT has been changing continuously, depending on current trends [15]. As the metabolic response to injury was increasingly investigated in the 1940s and 1950s, the cause of post-operative oliguria was widely debated by Moore and Shires, the most prominent surgeons [37]. During Vietnam War, the preservation of renal function, became a therapeutic objective, thus, allowing the use of large amounts of crystalloid for the hemorrhagic shock in the Da Nang Army Hospital. At this time pulmonary complications called Da Nang lung or wet lung syndrome, previous denominations of the present Adult Respiratory Distress Syndrome (ARDS), was observed which derived from prescribing large volumes of fluids.

These differences in opinion, coupled with reports on survival of injured soldiers from the Korean war who received large IV fluid infusions, dictated the surgical practice of liberal IV fluid administration until very recently [37]. Recent research in fluid therapy has explored the concept of fluid restriction. Shoemaker and colleagues also pioneered the concept of fluid administration to achieve supranormal indices of cardiorespiratory function, which has led to the advent of goal-directed fluid therapy [37].
Alongside the development of balanced solutions, the renewed focus on perioperative fluid therapy has led to IVF administration being guided by physiological principles with a new consideration of the lessons gleaned from history [37]. With military medicine advances, fluid therapy has attracted particular attention, and become increasingly important when it is combined with hemotherapy. But, with no clear ideas about the proper volume. Currently, fluid therapy stills with large controversies.

**Fluid Physiology**

The fundamentals governing fluid and electrolyte management in patients date to the 19th century [38]. In the first half of the 20th century work by Gamble and Darrow and colleagues defined the electrolyte content of extracellular, intracellular and interstitial fluid compartments [38]. The body of adult human contains 60% water, of which two-third is intracellular and the remaining one-third is in the extracellular space, which in turn is divided between intravascular and extravascular or interstitial compartments [39,40].

The interstitial compartment is actually a matrix, a collagen/gel substance that allows the interstitium to provide structural rigidity which resists against gravity and can maintain structural integrity during extracellular volume depletion. The collagen/gel interstitial space, especially in skin and connective tissue, is an important reservoir of extracellular fluid [38].

The total intravascular volume, also referred to as blood volume, is approximately 5 liters of which 2 liters (40%) form intracellular structures such as red and white cells and platelets and 3 liters (60%) constitute extracellular component (plasma) [39,40]. Extracellular compartment is important for oxygen and nutrients transport, and the elimination of carbonic anhydrase and other products from cellular metabolism. Another compartment is transcellular that includes fluids not equilibrated with the other fluids, and constitutes synovial, cerebrospinal fluids, gastrointestinal secretions, etc. This compartment through the lymphatic system returns the fluids to the intravascular space [40].

The cells and the intravascular space have membranes that preserve their structural integrity and allow the molecule and fluid interchange between different compartments. The main function of membranes is to preserve osmolarity and the electronegativity in of each compartment. The cell wall separates the intracellular space from the extracellular compartment. The capillary endothelium and the walls of arteries and veins divide the extracellular compartment into the intravascular and the interstitial areas such as tissue or extravascular compartments.

Water moves freely through cell and vessel walls and enters all these compartments. The energy-dependent Na/K adenosine triphosphatase in cell walls extrudes Na⁺ and Cl⁻ and maintains a sodium gradient across the cell membrane with Na⁺ as an extracellular ion. The capillary endothelium is freely permeable to small ions such as Na⁺ and Cl⁻, but is relatively impermeable to larger molecules such as albumin and the semisynthetic colloids like gelatin and starch, which normally remain in the intravascular space. Plasma is a solution in water of inorganic ions including predominantly sodium chloride, simple molecules such as urea, and larger organic molecules like albumin and the globulins. Plasma and interstitial fluid are highly interchangeable. Fluid exchange through a capillary is regulated by Starling’s law, which mathematically summarizes the forces governing the flow of fluid out of blood vessels into surrounding tissues, and expressed as

\[ Q_f = K_f \cdot (P_c - P_t) - R \cdot (\pi_c - \pi_t) \]

Where \( Q_f \) is the total fluid flux out of capillaries (not the quantity, but just the speed of water movement [16]) and \( K_f \) is the filtration coefficient (the product of the membrane conductance and the membrane surface area), \( P_c \) is intravascular hydrostatic pressure, \( P_t \) is interstitial hydrostatic pressure, \( \pi_c \) is colloid osmotic pressure within the vasculature, \( \pi_t \) is interstitial colloid osmotic pressure gradient across the vessel wall, and \( R \) is the oncotic reflection coefficient, the tendency of a membrane to impede the passage of oncotically active particles (Starling, 1896) [16,41]. \( R \) of 0 indicates a membrane that is totally permeable to protein while \( R \) of 1 represents a membrane that completely prevents protein diffusion.

Distribution terminates when the balance of the hydrostatic pressure and the osmotic pressure cancel each other out. Because the interstitium consists not only of free space but also of absorbent gel, captured water in the gel does not contribute to lowering the osmotic pressure in the interstitium [16]. Therefore, the osmotic pressure does not easily change until the gel is saturated by flow of water. This is a mechanism of edema formation. Thus, Starling’s law does not determine the distribution ratio between plasma and interstitium, it just explains the movement of water through the capillary wall [16].

The original interpretation of an equilibrium including fluid reabsorption at the venous end of the microcirculation is now known to be incorrect through actual measurement of the pressures involved. Rather, a steady state is involved, with a level of permeability to plasma proteins in the microvascular walls. Net fluid movement occurs in the vessels from the intravascular to the perivascular space [42]. The fluid transfer is mediated by the endothelial glycocalyx layer (EGL),
a physiological entity discovered and studied over the past 30 years [43]. A model for fluid transfer across the EGL [44] accounts for the discrepancies observed in fluid transfer as predicated by Starling’s original equation, and proposes a modified hypothesis based on pressures involving the generation of fluid through the glomerular rather than the interstitial space [45] modifying the Starling equation to:

\[ Q_f = (P_c - P_l) \cdot R \cdot (\pi_c - \pi_g) \]

Where \( P_l \) and \( \pi_g \) are the hydrostatic and osmotic pressures respectively, exerted by the formation of ultrafiltrate across the glomerular [46]. While the EGL is the conduit for water passage from the intravascular to the extravascular space, plasma proteins cross the endothelial barrier through a separate pathway, the large pore system [46].

This model is perturbed by a number of factors during anesthesia and surgery. Patients scheduled for surgery are presented with a variety of conditions that result in altered fluid distribution. Many anesthetic drugs like IV induction medications and volatile anesthetics cause vasodilation, leading to a reduction in the ratio between the circulating volume and the capacity of the intravascular space, or myocardial impairment, causing a reduction in flow through the circulation.

Fluid shifts between compartments may also reduce the circulating volume representing third-space losses and loss of intravascular fluid into the interstitium because of altered endothelial permeability in sepsis and inflammatory states [39].

The following section is devoted to a resume of the main characteristics of different kind of solutions.

**Crystalloids**

A crystalloid fluid is a solution of small water-soluble molecules that can diffuse easily across semi-permeable membranes. The properties of these solutions are largely determined by their tonicity (osmolality relative to plasma) and their sodium content (affecting their distribution within body compartments) [47]. They redistribute throughout the extracellular fluid (ECF) compartment, of which 75% is interstitial fluid. This suggests that 4 litres of crystalloid are required to replace a blood loss of 1 litre [48]. Studies have shown that the volume kinetics of infused crystalloid solutions differ between normovolaemic and hypovolaemic patients [49].

IV infusions of isotonic saline solution only expand the intravascular space by a maximum of one-third of the volume used in normal subjects, with only 16% left after 30 minutes. The volume of crystalloid required to replace an acute blood loss remains 3-4-fold because of redistribution into, and rapid elimination from, the ECF [48].

**Isotonic Solutions**

Isotonic or iso-osmolar solutions, with an osmolality \( \approx 300 \) mOsm/L, such as sodium chloride 0.9% (normal saline), Ringer’s solution or plasmaLyte, do not change plasma osmolality and do not increase brain water content [50]. They also contain sodium at physiological plasma concentrations. These fluids distribute freely within the ECF compartment causing little change in sodium concentration and osmolality. As a result, this limits the movement of water out of the extracellular fluid (ECF) into the intracellular fluid (ICF) compartment and vice versa. Commercial lactated Ringer’s solution is not truly iso-osmolar with respect to plasma. Its measured osmolality is \( \approx 254 \) mOsmol/kg, which explains why administration of large volumes can reduce plasma osmolality and increase brain water content and intracranial pressure (ICP) [50].

**Hypotonic Solutions**

Large amounts of hypo-osmolar or hypotonic fluids reduce plasma osmolality, drive water across the blood brain barrier (BBB), and increase cerebral water content and ICP. A solution of 5% dextrose (D5W) is essentially water since the sugar is metabolized very quickly and provides free water which disperses throughout the intracellular and extracellular compartments with little use as a resuscitative fluid [50]. Therefore, hypo-osmolar crystalloids (0.45% NaCl or D5W) should be avoided in neurosurgical patients [50].

**Hypertonic crystalloids: Mannitol and hypertonic saline**

Osmotherapy agents such as hypertonic saline (HTS) are currently used in the treatment of patients with post-traumatic cerebral edema and raised ICP resulting from TBI [51]. It is believed to have a particularly useful role in the treatment of ICP whilst administering small volume fluid resuscitation [52].

HTS solutions typically improve cardiovascular output as well as cerebral oxygenation whilst reducing cerebral oedema. Hypertonicity seems to affect some innate immune-cell functions, specifically neutrophil burst activity in preclinical studies, probably providing beneficial impact on modulation of the inflammatory response to trauma [53-58].

Clinical studies however do not provide compelling evidence to support the use of HTS either for TBI or for haemorrhagic shock. A small randomized clinical trial (RCT) reported a significant reduction in mortality when comparing a 250 ml bolus of HTS/dextran with isotonic saline in 222 patients with haemorrhagic shock [59]. But many other RCTs have not demonstrated reduction in mortality in this group of patients [60-63], including the most
recent and largest RCT comparing HTS, HTS/dextran and normal saline. This trial recruited two separate cohorts, one with TBI (n = 1087) [64] and the other with haemorrhagic shock (n = 853) [65]; with primary endpoints of neurological outcome at 6 months after TBI and 28 day survival respectively. The TBI study was terminated early due to futility, as interim analysis was unable to demonstrate an improvement in neurological status or indeed mortality at 6 months. Another study demonstrated no significant difference in mortality at 28 days, and was terminated early for concerns of potential (albeit statistically non-significant) increase in mortality observed with a subgroup of patients receiving HTS but no blood transfusions within the first 24 h [65]. Wade et al., [66] undertook a cohort analysis of individual patient data from a previous prospective randomized double-blinded trial to evaluate improvements in survival at 24 hours and discharge after initial treatment with HSD in patients who had TBI (head region Abbreviated Injury Score ≥4) and hypotension (systolic blood pressure <90 mm Hg). They found that treatment with HSD resulted in survival until discharge of 37.9% (39 of 103) compared with 26.9% (32 of 119) with standard care (p=0.080). Using logistic regression, adjusting for trial and potential confounding variables, the treatment effect can be summarized by the odds ratio of 2.12 (p=0.048) for survival until discharge. They concluded that patients with traumatic brain injuries in the presence of hypotension and receiving HSD are about twice as likely to survive as those who receive standard of care.

Rockswold et al., [67] examined the effect of hypertonic saline on ICP, cerebral perfusion pressure (CPP), and brain tissue oxygen tension (PbtO2), and found that hypertonic saline as a single osmotic agent decreased ICP while improving CPP and PbtO2 in patients with severe traumatic brain injury. Patients with higher baseline ICP and lower CPP levels responded to hypertonic saline more significantly.

Colloids

Colloids are fluids with larger, more insoluble molecules that do not readily cross semi-permeable membranes, across which they exert oncotic pressure. Water is drawn in from the interstitial and ICF by osmosis. Their movement out of the intravascular space and their duration of action is dependent on their molecular weight, shape, ionic charge and the capillary permeability [47]. Apart from albumin, all colloids are polymers and contain particles with different molecular weights [48]. They may increase plasma volume by more than the volume infused, because of their higher osmolality; hence the term plasma expanders [48]. Studies suggest they can cause significant impairment of clot formation activity [68,69].

Albumin

Albumin is a multifunctional, non-glycosylated, negatively charged plasma protein, with a molecular weight of 69 kD. It is a biological therapeutic, manufactured from an inherently variable material source using a variety of purification techniques. Albumin is an effective volume expander, has not been associated with allergic-type reactions, and has no intrinsic effects on clotting [50]. Its use as reanimation fluid has not been linked to better survival compared with the synthetic colloids, a fact that together with costs, discredits its use in critically ill patients [70]. There are in different concentrations: iso-oncotic (4.5% albumin) and hyper-oncotic (20% albumin). The later has adverse renal events.

Synthetic colloids

Gelatins

Gelatin products are semi-synthetic colloids derived from bovine collagen and prepared as polydispersive solutions by multiple chemical modifications [48,71]. Gelatins for volume therapy have been withdrawn from the US market due to the high rate of anaphylactic reactions [71]. Conventional gelatin preparations have a mean molecular weight of 30-35kDa and a low molecular mass range. Their intravascular persistence is short (2-3 hours), particularly for the urea-linked gelatins, with rapid renal excretion (80% molecules < 20 kDa). Since the cross-linked gelatin molecules contain negative charges, chloride concentrations of the solvent solution are reduced in contrast to other types of colloid. Since the latter fact results in slight hyposmolality, infusion of large amounts of gelatin solutions may reduce plasma osmolality and ultimately foster the genesis of intracellular edema [71]. The rapid urinary excretion of gelatin is associated with increased diuresis and has to be substituted by adequate crystalloid infusion to prevent dehydration. Gelatin infusion may furthermore increase blood viscosity and facilitate red blood cell aggregation without influencing the results of crossmatching. Severe anaphylactoid reactions are low (though more likely with gelatins than with other colloids), and usually occur only with rapid infusions (1/13000 for succinylated gelatin; 1/2000 for urea-linked gelatin), although much less with newer formulations. Reactions are usually mild (incidence < 0.4%).(48) Clinically, they have little effect on coagulation [48].

Dextran

These are neutral, high-molecular-weight
glucopolysaccharides based on glucose monomers. Dextran 40 is hyperoncotic and initially acts as a plasma expander before its rapid elimination by the kidney. Its main use is in promoting peripheral blood flow in cases of prophylaxis for deep vein thrombosis and arterial insufficiency. Dextran 70 and 110 are mainly used for plasma expansion; 6% dextran 110 is no longer available clinically. Blood flow improvement results from a reduction in blood viscosity, possibly by coating the vascular endothelium and cellular elements of blood, thus reducing their interaction. Dextran inhibits platelet adhesiveness, enhance fibrinolysis and may reduce factor VIII activity. Doses above 1.5 g/kg cause bleeding tendency. Initial use should be limited to 500–1000 ml with a restriction of 10–20 ml/kg/day thereafter.

Modern solutions do not interfere with blood cross-matching or cause roleaux formation, which was a feature of the early, very high MW dextran. They can impair renal function by tubular obstruction from dextran casts. This is usually seen with dextran 40 combined with hypovolaemia and pre-existing renal dysfunction. They can also cause an osmotic diuresis. Severe anaphylactic reactions like immune complex type III can occur resulting from prior cross-immunization against bacterial antigens forming dextran reactive antibodies. The incidence of 1/4500 is reduced with monovalent hapten pre-treatment (injection of 3 g dextran 1) to 1/84000. This blocks the antigen-binding sites of circulating antidextran antibodies, preventing formation of immune complexes with subsequent infusions of dextran 40 or 70. Dextran 1 (MW 1000 Da) is not available in the UK [48].

**Hydroxyethyl starch (HES)**

HES is a semi-synthetic colloid, related to glycogen and was used extensively to treat wounded soldiers during the Vietnam War (1959-1975) [71]. It is prepared from amylopectin, a highly branched polymer of glucose, derived from either waxy maize or potato starch [71], which are etherified with hydroxyethyl groups into the D-glucose units. HES have a much lower viscosity than dextran or gelatin, but do not reach the low viscosity of albumin. The mean molecular weight of the different HES preparations ranges from 70 and 670 kDa. Following infusion of HES, small molecules <60kDa are filtrated into the urine, whereas larger molecules are degraded by plasma amylase.

The kinetics of this degradation are mainly determined by the molar substitution and the C2/C6 ratio representing the quotient of the numbers of glucose residues hydroxymethylated at positions 2 and 6, respectively [71]. A high molar substitution and a high C2/C6 ratio make the HES molecule less susceptible to plasma amylase, and thus increase its intravascular half-life. Part of the HES is stored within the reticulo-endothelial system and slowly degraded to CO2 and water [71].

However, massive infusion of old, high-molecular-weight preparations with a high degree of substitution, particularly hexa- and hexastarch, may be associated with excessive tissue storage. With modern preparations such as 6% HES 130/0.4, no plasma accumulation and greatly reduced tissue storage have been reported in the literature [71]. The reduction in viscosity of HES solutions results from the globular structure associated with the high degree of branching [71]. They are classified as shown in Table 1. Different preparations of HES are hydrolysed to smaller molecules by amylase and renal elimination is rapid for polymers over 50 kDa. The action of amylase is suppressed by higher degrees of substitution and with greater etherification at the C2 versus C6 position. Intravascular half-life is thus maximized especially when the initial MW is high. In addition to the persistent plasma expansion, HES plug capillary leaks induced by sepsis and major trauma and restore macrophage function after hemorrhagic shock. Compared with 20% albumin in these patients, 10% HES significantly improves hemodynamic parameters in the systemic and microcirculation (splanchnic perfusion) [48].

**Fluid Therapy and Traumatic Brain Injury**

Clinically acceptable fluid restriction has little effect on edema formation. The first human study on fluid therapy demonstrated that reduction of 50% in

the standard’ maintenance volume in neurosurgical patients (2.000 mL/day of 0.45 normal saline in 5% dextrose) increases serum osmolality over about a week [72]. Thus the old concept of benefit from fluid restriction was simply a consequence of an increased osmotic gradient over time [50]. The available data indicate that volume replacement and expansion will have no effect on cerebral edema as long as normal serum osmolality is maintained, and cerebral hydrostatic pressures are not markedly increased due to true volume overload and elevated right heart pressures. Whether this is achieved with crystalloid or colloid seems uncertain, although the osmolality of the selected fluid is crucial. As previously mentioned, lactated Ringer’s solution is not strictly iso-osmotic (measured osmolality 252-255 mOsmol/kg), particularly when administered to patients whose baseline osmolality has been increased by hyperosmolar fluids (mannitol, HS) [50].

In TBI, a blunt or penetrating injury incites mechanical and autodigestive destruction of the normally tightly intact endothelium of the blood brain barrier [73]. This allows uncontrolled movement of fluid and serum proteins into the brain parenchyma, eventually leading to vasogenic cerebral edema and increased ICP. It has been shown that in critically ill patients, there is increased leakage of albumin across the capillary wall [74]. In the brain, this increased extravasation of albumin could lead to heightened interstitial onotic pressure and exacerbate cerebral edema.

Pre-hospital
In nine randomised controlled trials and one cohort study of pre-hospital fluid treatment in patients with TBI [75], hypertonic crystalloids and colloid solutions were not more effective than isotonic saline [76]. In a combined polytrauma model of uncontrolled haemorrhage and TBI in swine, Teranishi et al., [6] investigated if pre-hospital administration of the haemoglobin based oxygen carrier HBOC-201 will improve tissue oxygenation and physiologic parameters compared to LR solution. They found that mean TBI force (2.4±0.1 atm; means ± standard error of the mean) and blood loss (22.5±1.7 mL/kg) were similar between groups. Survival at the 6th endpoint was similar in all groups ( ~80%). Cerebral perfusion pressure (CPP) and brain tissue oxygen tension were significantly greater in HBOC-201 as compared with LR animals (p<0.005). Mean arterial pressure (MAP) and mean pulmonary artery pressure (MPAP) were not significantly different amongst groups. Blood transfusion requirements were delayed in HBOC-201 animals. Animals treated with HBOC-201 or LR showed no immunohistopathological differences in glial fibrillary acidic protein (GFAP) and microtubule-associated protein 2 (MAP-2). Severity of subarachnoid and intraparenchymal haemorrhages were similar for HBOC and LR groups. They concluded from their polytrauma swine model of uncontrolled haemorrhage and TBI with a 30-min delay to hospital arrival, pre-hospital resuscitation of patients by one bolus of HBOC-201 indicated short term benefits in systemic and cerebrovascular physiological parameters. True clinical benefits of this strategy need to be confirmed on TBI and haemorrhagic shock patients.

In-hospital
A defined strategy for volume replacement and fluid balance that includes maintenance of normovolemia and colloid osmotic pressure in combination with a neutral to a slightly negative fluid balance is a cornerstone of the intracranial pressure (ICP)-targeted therapy for severe TBI [77]. In contrast to hemorrhage and hemorrhagic shock, possibilities for life-saving interventions are very limited in CNS injury. The significant contribution of HS to brain injury mortality further illustrates the role of hemorrhage control in reducing mortality in trauma patients [78].

Crystalloid resuscitation should be targeting a corridor of safety, avoiding both extremes of overt hypovolaemia and fluid overload. While avoidance of edema formation is a prime objective and concern in visceral surgery, efforts to restrict fluids, such as ‘forced hypovolaemia’, are associated with oliguria and occasionally renal shutdown, and may impair nutritional microvascular blood flow in other vascular beds such as the splanchic circulation. Fluid excess, on the other hand, is presumably a cause of perioperative morbidity and mortality [79]. Sequelae of volume overload are particularly well known, and the pathophysiological cascades of events have been worked out best for the patient with aggressive crystalloid resuscitation after major trauma: Manifestations of crystalloid overload might include ARDS and brain edema in the patient with concomitant head injury [80-84].

Wahlström et al., [77] analyzed the occurrence of organ failure and mortality in patients with severe TBI treated by a protocol that includes defined strategies for fluid therapy including albumin administration to maintain normal colloid osmotic pressure and advocating a neutral to slightly negative fluid balance. Studies conducted on 93 patients with severe TBI and Glasgow Coma Scale (GCS) ≤8 during 1998-2001 retrieved the medical records of patients in the first 10 days. Organ dysfunction was evaluated with the Sequential Organ Failure Assessment (SOFA) score.
Mortality was assessed after 10 and 28 days, 6 and 18 months. They found that the total fluid balance was positive on days 1-3, and negative on days 4-10, and the crystalloid balance was negative from day 2. The mean serum albumin was 38±6 g/L. Colloids constituted 40-60% of the total fluids given per day. Furosemide was administered to 94% of all patients. Severe organ failure defined as SOFA ≥3 was evident only for respiratory failure, which was observed in 29% with none developing renal failure. After 28 days, mortality was 11% and, after 18 months, it was 14%. Thus, a protocol including albumin administration combined with a neutral to a slightly negative fluid balance was associated with low mortality in patients with severe TBI despite a relatively high frequency (29%) of respiratory failure, assessed by the SOFA.

Acute lung injury (ALI) and ARDS are reported commonly after TBI and their appearance is associated with fluid management. ALI and ARDS are considered as independent factors for mortality [85-88].

A single equimolar infusion of 7.45% hypertonic saline solution is as effective as 20% mannitol in decreasing ICP in patients with brain injury [79]. In the Taiwan guidelines for TBI management, with needed massive fluid transfusion, it is recommended that normal saline is better than lactated Ringer's solution (grade D). Fresh frozen plasma is only indicated for coagulopathy and not used as a regular volume expander (grade C). Hypertonic saline may be useful in patients with complication of severe TBI and systemic shock (grade D) [89].

The Saline versus Albumin Fluid Evaluation (SAFE) study was an international trial that randomized critically ill patients to either 4% albumin or normal saline fluid resuscitation for 28 days [89]. Although there was no overall difference in 28-day mortality between the 2 groups, there was a trend toward increased mortality in patients with trauma randomized to albumin resuscitation. This increased mortality appeared to be driven by patients with trauma with TBI compared with those with trauma without TBI. A post hoc analysis of patients with TBI randomized during the SAFE study confirmed that resuscitation with albumin was associated with increased mortality at 24 months compared with normal saline [90-92]. This increased risk was entirely driven by patients with severe TBI, defined as GCS <8. Sekhon et al., [91] in their study on 171 patients attempted to determine if there was an association between synthetic colloids and mortality in patients with severe TBI, and found that patients receiving pentastarch had higher acute physiology and chronic health II scores (23.9 vs 21.6, p<0.01), frequency of craniotomy (42.5% vs 21.6%, p=0.02), longer duration of intensive care unit stay (12 vs 4 days, p<0.01), and mechanical ventilation (10 vs 3 days, p<0.01). On unadjusted Cox regression, patients in the highest quintile of cumulative pentastarch administration had a higher rate of mortality compared with those receiving no colloid (hazard ratio, 3.8; 95% confidence interval, 1.2-12.4; p=0.03). However, this relationship did not persist in the final multivariable model (hazard ratio 1.0; 95% confidence interval, 0.25-4.1; p= 0.98). They concluded that there was no association between cumulative exposure to pentastarch and mortality in patients with severe TBI.

Elliot et al., [51] in a study focused on the hypothesis that hypertonic saline-induced improvements in histological outcome are time dependent and may be associated with alterations in astrocyte hypertrophy after cortical contusion injury. They examined histopathological changes at 7 days after controlled cortical impact (CCI) injury in a rat model and found that hypertonic saline treatment reduced tissue loss. This correlated with attenuated astrocyte hypertrophy characterized by reductions in astrocyte immunoreactivity without changes in the number of astrocytes after CCI injury. Delayed treatment of hypertonic saline resulted in the greatest reduction in tissue loss compared to all other treatments [0.9% normal saline (NS; n=12), 7.5% hypertonic saline (HS; n=15), delayed NS (n=3), delayed HS (n=4), or no treatment (CCI control; n=18)] indicating that there was a therapeutic window for hypertonic saline use after TBI.

**Hypertonic/hyperoncotic solutions**

Recently, attention has been directed at hypertonic/hyperoncotic solutions typical of hypertonic hetastarch or dextran solutions. Because of the haemodynamic stabilizing properties of these fluids in hypovolaemic shock, their administration in patients with trauma and TBI might be particularly advantageous for the prevention of secondary ischaemic brain damage. Small volumes of such solutions can rapidly restore normovolaemia without increasing ICP. They have been successfully used to treat intracranial hypertension in TBI patients [66], and in other neurological acute emergencies [SAH [92] and stroke [93]].

**Fluid Therapy for Decompressive Craniectomy**

Some general principles of enhanced recovery associated with fluid management and recommendations for the enhanced recovery partnership are as follows [94]:

**Pre-operative:**
- Maintain good pre-operative hydration.
Fluid therapy in traumatic brain injury

Surgery alters fluid balance [39], generates a systemic inflammatory response which increases oxygen consumption, and is associated with increase in cardiac output and oxygen delivery. Failure to meet the metabolic demands of recovery from surgery is associated with increased morbidity and mortality [95]. The stress response to surgery and trauma involves a number of different physiological reactions. Importantly, the renine-angiotensine-aldosterone system is stimulated, leading to increased sodium and fluid retention, decreased urinary output and altered fluid balance. In addition, the activated inflammatory response causes vasodilatation and increased permeability of capillary wall [47]. This affects the intravascular duration of fluids administration, with increased capillary leak of fluids into the interstitial tissues. As a result, the perioperative period is a time when the body’s management of fluids is dramatically altered and needs to be considered carefully when prescribing fluids [47].

In conclusion, perioperative fluid therapy continues to be an exercise in empiricism, with nagging questions about its efficacy and complications. There are no evidence-based guidelines or standards of care for the management of fluid therapy in patients undergoing decompressive craniectomy. Knowledge of the properties of the various available IV fluids, and the awareness of the pathophysiology of endothelial, parenchymal and endocrine alterations emerging in TBI should guide i.v. fluid administration, to reach a good medium that favors better neurological, morbidity and mortality outcomes.

Conflict of Interest: None declared.
